## AUDIENCE CROSSOVER: MEDIA PARTICIPATION AND ATMENDING LIVE EVENTS

The final results of the 1982 Survey of Public Participation in the Arts are now being analyzed in many differeat ways. One objective is to improve audience development tools and a relevant question is:

Do media audiences also attend live arts events?
This Note compares 112 pairs of electronic media activities and live activities in terms of a statistical technique known as the Pearson Correlation Coefficient. This kind of statistic has not been used in previous Research Division Notes, so a brief explanation may be helpful.

Technically speaking, correlation coefficients (Pearson's r) measure the degree to which the relationsinip between two variables can be represented by a straight line. In teris of this Note, they show whether attending a live arts event goes along nere or less closely with one of the kinds of electronic media participation. The range of possible values is +1.000 to -1.000. When the coefficient is positive, the two activities increase or decrease together, but if one activity increases as the other decreases, the coefficient is negative. The middle of the range is 0.000 , and describes a relationship that is totally nonlinear. A pair of activities with this neutral ccefficient do not go along with each other with any consistency.

In the real world, perfect straight line relationships rarely occur, so the values of coefficients are usually smeller than $1.000(+/-)$. As a guide:

$$
\begin{aligned}
& \text { Correlations of } .400(+/-) \text { or greater are "strong"; } \\
& \text { Correlations of } .300(+/-) \text { to } .399(+/-) \text { are "substantial"; } \\
& \text { Correlations of } .200(+/-) \text { to } .299(+/-) \text { are "moderate"; and } \\
& \text { Correlations of }+.199 \text { to }-.199 \text { are "weak". }
\end{aligned}
$$

Keep in mind that the correiation coefficient values are not measurements on a scale of equal units. A change in coefficients from . 000 to +.200 shows less change in closeness to a straight line than a change from +.200 to +.400 .

One use for correlation coefficients is to pradict participation in one activity from knowing about participation in another activity. Por example, the correiation coefficient of +.343 for listening to classical music records and attending live classical music concerts is a "substantial" predictor that the population doing one will also do the other. On the other hand, the correlation coefficient of +.098 for listening to jazz music on radio and attending live ballet performances is a "weak" predictor although it is positive. You can now read and interpret the table yourself, but to start, here are a few interesting observations:

All 112 correlation coefficients for pairs of media and live activities are positive. They shov that when participation in one increases or decreases, so should participation in the other.

However, for the most part, the coefficients indicate moderate or weak correlations. Not one of the correlations in the table can be considered to be strong and only five are substantial with coefficients of between . 300 and .399 .

The correlation in the table closest to being strong is for listening to jazz music records and attending jazz music performances ( +.351 ). The next two substantial correlations are for listening to classical music records and attending classical music concerta ( +.343 ), and for listening to classical music records and visiting art museums (+.343).

There are seven negative correlation coefficients in the table. These are for tie total of hours spent watching all TV and attending live arts events. Since they are negative, they show that as the amount of time spent watching all TV incrasaes, attendance at live arts events decreases. However, all of these coefficients are weak, indicating that predictions about time spent watching TV and attendance at live events cannot be precise (doing one is a poor predictor of not doing the other).

For arts administrators engaged in audience development, the study of these correlation coefficients may suggest several possibilities to sharpen the focus of their efforts. At present, many development officers in arts organizations are finding that the returns are dropping from rapidy increasing development expenditures. While the study of the correlation coefficients table in this Note may not reverse this unhappy experieace, it may suggest new strategies in a few areas.

For exampie, the audience for jazz music records correlates substantially with the audience for live jazz music concerts, but except for classical music no other pairing of listening to records and attending live performances comes close to being equally strong.

On the other hand, the table shows that the correlation between listening to classical music records and attending art museums is just as cloge as attending live performances of classical music. This suggests many possibilities, e.g., selling classicsi music records in art museum shops, eapecially when the music genre may be related to a special exhibit; and using art museum membership lists to promote symphony orchestra ticket sales or using lists of classical chamber music subscribers to promote art museum membership.

One surprise is that the correlation betreen attending art mugeums and participation via the media is often stronger than the corralation between attending live performances and media participation in a similar art form. For example, the correlation between watching ballet on $T V$ with attendance at live ballet perfomances is not as atrong as with attending art museums.

Awareness that many of the correlations are weak can also be useful. They caution against making broad generslizations about relationships that may not really apply across different art forms. This may help sharpen the focus of promotional efforts.

From a more global point of view, study of the table of correlation coefficients is very intriguing because it reveals some of the complexity in the relationships between audiences. Comparing such tables from one time period to the nert, as we will do when the current 1985 survey is completed, should reverl patterns of change in audience crossover.

CAVEAT: The Pearson Correlation Coefficient is mathematical analytical tool and useful as it may be, it is only an indicator of the great complerity of crossover relationships. There are also other techniques that also can be used to give additional perspectives, One of these is called Odds-Ratios Analysis. It gives results in terms of the probability that survey respondents attending one live event will aiso do one of the other activities in the table. Future Research Division Notes will examine some of these aiternative analytical tools and the insignts they may add.
